ASSIGNMENT 1

OS344 - Operating Systems Laboratory

G4 Group Members:

1.	B Venkatesh	180101013
2.	Harsh Motwani	180101028
3.	Nishchay Manwani	180101051
4.	Vaibhav Kumar Singh	180101086

Part 1: PC Bootstrap

1.

```
PS C:\Users\zeus_iitg\Desktop\os report> gcc ex1.c
PS C:\Users\zeus_iitg\Desktop\os report> ./a.exe
Hello x = 1
Hello x = 2 after increment
OK
```

Added code:

```
1. __asm__ ( "addl %%ebx, %%eax;"
2. : "=a" (x)
3. : "a" (x), "b" (1) );
```

In this, x and 1 are the input operands while x is the output operand. This code adds the value of x and 1 and saves the output to x. Hence, incrementing the value by 1.

The "si" instruction in gdb is used to execute one machine instruction (follows a call). The above screenshot shows the first 4 instructions of the xv6 operating system. The first instruction is

[f000:fff0] 0xffff0: ljmp \$0x3630,\$0xf000e05b

Here, f000 is the **Starting Code Segment**, fff0 is the **Starting Instruction Pointer**, 0xffff0 is the **Physical Address** where this instruction resides, 1jmp is the **Instruction**, 0x3630 is the **Destination Code Segment**, 0xf000e05b is the **Destination Instruction Pointer**.

The **cmp** instruction is used to perform comparison. It's identical to the sub instruction except it does not affect operands.

The **jnz** (or **jne**) instruction is a conditional jump that follows a test. It jumps to the specified location if the Zero Flag (ZF) is cleared (0). jnz is commonly used to explicitly test for something not being equal to zero whereas jne is commonly found after a cmp instruction.

The **xor** instruction performs a logical XOR (exclusive OR) operation. This is the equivalent to the "^" operator in python.

Part 2: The Boot Loader

3. The code for readsect() is given below

```
1. // Read a single sector at offset into dst.
2. void
3. readsect(void *dst, uint offset)
4. {
5.  // Issue command.
6. waitdisk();
```

```
7.  outb(0x1F2, 1);  // count = 1
8.  outb(0x1F3, offset);
9.  outb(0x1F4, offset >> 8);
10.  outb(0x1F5, offset >> 16);
11.  outb(0x1F6, (offset >> 24) | 0xE0);
12.  outb(0x1F7, 0x20);  // cmd 0x20 - read sectors
13.
14.  // Read data.
15.  waitdisk();
16.  insl(0x1F0, dst, SECTSIZE/4);
17. }
```

```
waitdisk();
     7c9c:e8 dd ff ff ff
                               call 7c7e <waitdisk>
   outb(0x1F2, 1); // count = 1
4.
   outb(0x1F3, offset);
   outb(0x1F4, offset >> 8);
   7cb4:89 d8
                               mov %ebx, %eax
     7cb6:c1 e8 08
                               shr $0x8,%eax
    7cb9:ba f4 01 00 00
7cbe:ee
                               mov $0x1f4,%edx
                               out %al, (%dx)
10. outb(0x1F5, offset >> 16);
      7cbf: 89 d8
                                             %ebx, %eax
                                      mov
       7cc1:
                 c1 e8 10
                                            $0x10,%eax
                                       shr
      7cc4:
7cc9:
                 ba f5 01 00 00
                                      mov
                                           $0x1f5, %edx
                                            %al,(%dx)
                 ee
                                       out
    outb(0x1F6, (offset >> 24) | 0xE0);
     7cca: 89 d8
7ccc: c1 e8 18
                                             %ebx, %eax
                                      mov
       7ccc:
                                            $0x18,%eax
                                       shr
      7ccf:
                 83 c8 e0
                                            $0xffffffe0,%eax
                                       or
                ba f6 01 00 00
                                     mov
       7cd2:
                                             $0x1f6, %edx
       7cd7:
                                             %al, (%dx)
                 ee
                                       out
       7cd8:
                 b8 20 00 00 00
                                             $0x20, %eax
                                       mov
      7cdd:
                 ba f7 01 00 00
                                       mov
                                             $0x1f7, %edx
     7ce2:
                  ee
                                       out
                                             %al, (%dx)
    outb (0x1F7, 0x20); // cmd 0x20 - read sectors
     waitdisk();
                 e8 96 ff ff ff
                                       call 7c7e <waitdisk>
      insl(0x1F0, dst, SECTSIZE/4);
```

The assembly code for readsect() is given above. Now we will discuss about the for loop that reads the sectors of kernel from the disk. The code is given below:

```
for(; ph < eph; ph++){
   pa = (uchar*)ph->paddr;
   readseg(pa, ph->filesz, ph->off);
   if(ph->memsz > ph->filesz)
     stosb(pa + ph->filesz, 0, ph->memsz - ph->filesz);
}
```

The first instruction of this for loop is

```
1. 7d8d: 39 f3 cmp %esi,%ebx
```

The last instruction of this for loop is

```
1. 7da4: 76 eb jbe 7d91 <bootmain+0x48>
```

The explanation for the first instruction is that the first operation on entering the for loop will be comparison between the values of ph and eph because the loop will run only when ph < eph. The explanation of last instruction is that the loop ends when the values of ph and eph become equal and hence the loop jumps to the next instruction at 0x7d91. Hence the jump instruction will be the last instruction of the for loop. The next instruction after the for loop is

```
1. 7d91: ff 15 18 00 01 00 call *0x10018
```

Making a breakpoint at that address and then stepping into further instructions gives the following output.

```
zeus-iitg@zeus-iitg-LENOVO-Legion-Y540: ~/xv6-public 🔍 🗏

```
Switch from real to protected mode. Use a bootstrap GDT that makes
  # virtual addresses map directly to physical addresses so that the
  # effective memory map doesn't change during the transition.
 lgdt
         gdtdesc
         %cr0, %eax
$CR0_PE, %eax
 movl
 movl
  # Complete the transition to 32-bit protected mode by using a long jmp
 # to reload %cs and %eip. The segment descriptors are set up with no
 # translation, so that the mapping is still the identity mapping.
         $(SEG_KCODE<<3), $start32</pre>
.code32 # Tell assembler to generate 32-bit code now.
 # Set up the protected-mode data segment registers
          $(SEG_KDATA<<3), %ax
                                  # Our data segment selector
```

- (a) By analysing the contents of bootasm.S, we reach the following conclusion. "movw \$(SEG_KDATA<<3), %ax" is the first instruction to be executed in 32-bit mode. "ljmp \$(SEG_KCODE<<3), \$start32" instruction completes the transition to 32-bit protected mode.
- (b) By analysing the contents of bootasm.S, bootmain.c and bootblock.asm, we conclude that bootasm.S switches the OS into 32-bit mode and then calls bootmain.c which first loads the kernel using ELF header and the enters the kernel using entry(). Hence the last instruction of bootloader is entry(). Looking for the same in bootblock.asm, we find out the instruction to be

```
1. 7d91: ff 15 18 00 01 00 call *0x10018
```

which is a call instruction which shifts control to the address stored at 0x10018 since **dereferencing operator** (*) has been used. Now we need to know the starting address of the kernel. We can find this by two methods:

- (i) By looking at the first word of memory stored at 0x10018 (by using the command "x/1x 0x10018")
- (ii) By looking at the contents of "objdump -f kernel"

After getting the starting address of kernel, we need to see what is the instruction stored at that address to get the first instruction of kernel. We can do this by two methods:

- (i) By using "x/1i 0x0010000c"
- (ii) By looking into kernel.asm

Hence, the first instruction of kernel is

```
1. 0x10000c: mov %cr4,%eax
```

(c)

```
// Load each program segment (ignores ph flags).

ph = (struct proghdr*)((uchar*)elf + elf->phoff);

eph = ph + elf->phnum;

for(; ph < eph; ph++){

  pa = (uchar*)ph->paddr;

  readseg(pa, ph->filesz, ph->off);

  if(ph->memsz > ph->filesz)

    stosb(pa + ph->filesz, 0, ph->memsz - ph->filesz);
}
```

The above lines of code are present in bootmain.c. This is the code that is used by xv6 to load the kernel. xv6 first loads ELF headers of kernel into a memory location pointed to by "elf". Then it stores the starting address of the first segment of the kernel to be loaded in "ph" by adding an offset ("elf->phoff") to the starting address (elf). It also maintains an end pointer eph which points to the memory location after the end of the last segment. It then iterates over all the segments. For every segment, pa points to the address at which this segment has to be loaded. Then it loads the current segment at that location by passing pa, ph->filesz and ph->off parameters to readseg. It then checks the memory assigned to this sector is greater than the data copied. If this is true, it initializes the extra memory with zeros.

Coming back to the question, the boot loader keeps loading segments while the condition "ph < eph" is true. The values of ph and eph are determined using attributes phoff and phnum of the ELF header. So the information stores in the ELF header helps the boot loader to decide how many sectors it has to read.

4.

```
zeus-iitg@zeus-iitg-LENOVO-Legion-Y540:~/xv6-public$ objdump -h kernel

As we can see in the above screenshot, VMA and LMA of .text section is same indicating that it loads and executes from the same address.

5. I changed the link address from 0x7c00 to 0x7c08. Since no change has been done to the BIOS, it will run smoothly for both of the versions and hand over the control to the boot loader. From this point onwards, we have to check for differences between the two files. I did it by using si command repeatedly to get the next 200 (approx.) instructions and then comparing the outputs of the two files. The first command where a difference was spotted is shown below along with the next 3 instructions. The first picture is when the link address was correctly set to 0x7c00 and the second picture is when it was

changed to 0x7c08. I have attached the output files of gdb in my submission. I have also attached output files of "objdump -h bootmain.o" for both of the versions since the outputs differ due to the change in link address.

```

6. For this experiment, we have to examine the 8 words of memory at 0x00100000 at two different instances of time, the first when the BIOS enters boot loader and the second when the boot loader enters the kernel. For this, we will use the command "x/8x 0x00100000" but before that we will have to set our breakpoints. The first breakpoint will be at 0x7c00 because this is the point where the BIOS hands control over to the boot loader. The second breakpoint will be at 0x0010000c because this is the point when the kernel is passed control by the bootloader.

                                0x00000000
                                                                 0x00000000
                                                0x00000000
(gdb) b *0x0010000c
Breakpoint 2 at 0x10000c
(gdb) c
Continuing.
The target architecture is assumed to be i386
=> 0x10000c:
                      %cr4,%eax
               mov
Thread 1 hit Breakpoint 2, 0x0010000c in ?? ()
(gdb) x/8x 0x00100000
                                                0xe4524ffe
                0x1badb002
                                0x00000000
                                                                 0x83e0200f
                                0xa000b8e0
                                                0x220f0010
                0x220f10c8
                                                                 0xc0200fd8
```

As we can see in the diagram, we get different values at both the breakpoints. The explanation to this is as follows. The address 0x00100000 is actually 1MB which is the address from where the kernel is loaded into the memory. Before the kernel is loaded into the memory, this address contains no data (i.e. garbage value). By default, all the uninitialized values are set to 0 in xv6. Hence, when we tried to read the 8 words of memory at 0x00100000 at the first breakpoint, we got all zeroes since no data had been loaded until that point. When we check the values at the second breakpoint, the kernel has already been loaded into the memory and thus this address now contains meaningful data instead of zeroes.

Part 3: Adding a System Call

7. An operating system supports two modes; the kernel mode and the user mode. When a program in user mode requires access to RAM or a hardware resource, it must ask the kernel to provide access to that particular resource. This is done via a system call. When a program makes a system call, the mode is switched from user mode to kernel mode.

In order to define our own system call in xv6, changes need to be made to 5 files. Namely, these files are as follows.

- (i) syscall.h
- (ii) syscall.c
- (iii) sysproc.c
- (iv) usys.S
- (v) user.h

We would start the procedure by editing syscall.h in which a number is given to every system call. This file already contains 21 system calls. In order to add the custom system call, the following line needs to be added to this file.

```
1. #define SYS_wolfie 22
```

Next, we need to add a pointer to the system call in the syscall.c file. This file contains an array of function pointers which uses the above-defined numbers (indexes) as pointers to system calls which are defined in a different location. In order to add our custom system call, add the following line to this file.

```
1. [SYS_wolfie] sys_wolfie,
```

When the system call with number 22 is called by a user program, the function pointer sys_wolfie which has the index SYS_wolfie or 22 will call the system call function. Hence, our next objective is to implement a system call function. But we do not implement the system call function in syscall.c. We only add a prototype as shown below.

```
1. extern int sys_wolfie(void);
```

We implement the system call function in sysproc.c.

Now, to add an interface for a user program to call the system call, we add

```
1. SYSCALL(wolfie)
```

to usys.S and

```
1. int wolfie(void*, uint);
```

to user.h

8. Now the only task left is to add a user program to call the system call that we just made above. For this, I made a file wolfietest.c inside xv6 folder and wrote the following code in it.

```
#include "types.h"
#include "stat.h"
#include "user.h"

int
main(void)
{
    static char buf[2000];
    printf(1, "wolfie sys call returns %d\n", wolfie((void*) buf,2000));
    printf(1, "%s", buf);
    exit();
}
```

After this, I added this file to the Makefile under UPROGS and EXTRA.

Then I used "make clean", "make", "make qemu-nox" and then entered wolfietest to get the following output. Also, my program is also listed when I use the Is command. Screenshot is attached below.
